A b s t r a c t. The flight activity of bats was studied at 21 localities in the Moravian Karst (Czech Republic). From April to October, bat detectors were used to record echolocation calls of bats on line transects during the first half of the night. Nine habitats were distinguished. In total, 666 minutes of the presence of flying bats and at least 16 bat species were registered during 3387 transect minutes. Myotis daubentonii was the most numerous species (46.2%). The number of bat species was the highest in rocky habitats (13 species), and the lowest in agrocoenoses (3 species). The greatest intensity of flight activity of the bat community was observed over ponds (35.0 min+/h) and streams (26.6 min+/h). With respect to habitat preference, M. mystacinus/brandtii, M. myotis/blythii, Eptesicus serotinus, Nyctalus noctula, Pipistrellus pipistrellus, and Plecotus auritus/austriacus appear to be eurytopic and M. daubentonii, M. nattereri and M. emarginatus to be stenotopic species.

Key words: Moravian Karst, echolocation calls, bat community, detectoring, line transect

Introduction

During the past decade, an increased number of articles was published on the habitat preference and activity of bat communities (Walsh & Harris 1996, von Zahn & Mayer 1997, Gaissler et al. 1998). This is due to the expansion of ultrasound detector use in field research, including studies in such highly diversified landscapes as karstic regions. While the use of bat detectors has become established the standard methods of carrying out research in bat activity (Ahlen & Baagoe 1999) it has its intrinsic technical (different types of signal transformation) and ecological (whispering bat species, direction of signals etc.) constraints which could more or less influence the study results (Hayes 2000, Gannon et al. 2003). The most frequently designs used in field research include the transect method (Gaissler & Kolibáč 1992, Walsh & Harris 1996, Verboum 1998), which was adopted from ornithology, and/or the point method (Walsh & Mayle 1991, Rauthwald 1992, Rydell et al. 1994).

Bats forage in various types of habitats, from forest habitats up to villages, and the spatial distribution of bat activity is mainly determined by the distribution of their prey (Rydell 1992). Habitat selection is also influenced by the ability of various bat species to exploit these habitats, depending on their structure or their accessibility (de Jong 1995, Verboum 1998, Kusch et al. 2004). Among insectivorous bats, the following five foraging strategies based on wing morphology and structure of echolocation calls (Norberg & Rayner 1987, Fenton 1990) can be identified: fast and slow aerial hawking, flycatching, trawling, and gleaning. Many bat species can use more than one
foraging technique. Most central European bat species forage by aerial hawking, often with the addition of one or more other techniques (Norberg & Rayner 1987).

The bat fauna of the Moravian Karst is characterized by high density and diversity. So far, this phenomenon has only been explained by the large number of caves in this area (ca. 1200), but they are used by bats mainly as hibernacula (Zima et al. 1994). Nevertheless, there is a mosaic of various habitats under different anthropogenic impact and this fact permits the presence of a rich bat community even during the non-hibernating period.

The purpose of this study was to obtain data on the flight activity of bats during the non-hibernating period in various habitats of the karstic area under study. The landscape of the Moravian Karst is subject to management as part of the agricultural, hydrological and recreational demands of tourism. By assessing the relative importance of the particular habitats for bat distribution, it should be possible to improve the landscape management system in favour of the bats.

Material and Methods

The flight activity of bats was studied in 21 localities in all parts of the Moravian Karst area (Central Moravia, Czech Republic) (Table 1). The size of this karstic area is 85 km². Nine habitat types were distinguished for the comparison of bat activity: fields (fi), meadows (m), linear landscape elements (l), villages (v), rocks (r), forests (fo), edges of forest (e), streams (s), and ponds (p).

Bat detectors (Pettersson Elektronik, D100 and D980) were used to record echolocation calls of bats on the line transects. The transects were mostly carried out during the first half of the night from April to October of 1992–1994. The number of minutes during which a particular species or two sibling species was registered, related to 1 hour of transect (min+/h), was used as the measure of bat activity (McAney & Fairley 1988).

With regard to the difficult determination of some of the bat species in the field, the transects were conducted simultaneously by two researchers using two detectors. Where appropriate, we made records for comparison with reference records (Ahlen 1987). Foraging behaviour was also included in the process of species identification when we tried to catch flying bats in the beam of a halogen lamp.
In order to group bat species that use similar foraging habitats, we performed a cluster analysis using the complete linkage method (Euclidean distance) (Z a r 1984). The same type of clustering (complete linkage) was also applied to the matrix of Renkonen’s index of dominance similarity (dominance of particular bat species) to compare the habitat types under study. In order to provide a comprehensive account of bat species-habitat association (bat species recorded for over 10 min+ in the total sample of 11 hours), the data on total bat activity in various habitats were subjected to canonical correspondence analysis.

Results

In total, 666 minutes of bat activity were registered by bat detectors during 3387 transect minutes (68 monitoring nights). At least 16 bat species were recorded, viz., *Rhinolophus hipposideros* (Rh), *Myotis mystacinus/brandtii* (Ms), *M. emarginatus* (Me), *M. nattereri* (Mn), *M. bechsteinii* (Mb), *M. myotis/blythii* (Mm), *M. daubentonii* (Md), *Vespertilio murinus* (Vm), *Eptesicus nilssonii* (En), *E. serotinus* (Es), *Nyctalus leisleri* (Nl), *N. noctula* (Nn), *Pipistrellus pipistrellus* (Pp), *P. nathusii* (Pn), *Barbastella barbastellus* (Bb), *Plecotus auritus/austriacus* (Pa). In field work, the two species of *Pipistrellus* i.e. *P. pipistrellus* and *P. pygmaeus* were not distinguished but later analyses revealed the presence of both species in the area under study, with the absolute predominance of *P. pipistrellus*.

The greatest intensity of flight activity of bats was observed over ponds (41.1 min+/h) and streams (26.3 min+/h) (Fig. 1). The interior of villages was another important habitat showing high flight activity of flying bats, above all, near streetlamps (11.2 min+/h). However, agrocoenoses lacking patches of trees or shrubs were poorly used by bats (2.7 min+/h).

The greatest intensity of flight activity was recorded in *M. daubentonii* (52.1 min+/h), especially at watersides (Fig. 2). Further species with relatively high activity included *Pipistrellus pipistrellus* (13.3 min+/h) and *Eptesicus serotinus* (11.6 min+/h), which are able to exploit a wider variety of habitats as foraging sites. On the other hand, *E. nilssonii* and *Vespertilio murinus* represent very rare faunistic records of these bat species in the area.

Cluster analysis divided habitat types into four groups (Fig. 3). The first group consists of water habitats, showing the specific structure of the bat community which was dominated by *M. daubentonii*. Fields, being highly influenced anthropogenic habitat types, are used by bats only for sporadic passes. Like the villages, this habitat is specific and separated. However the villages are providing roosts and foraging sites for synanthropic bat species. Cluttered and semi-cluttered habitats with similar bat communities (mainly forest-dwelling species) formed the last group.

Comparisons of the flight activity of nine common bat species or species pairs (over 1% of total sample) in particular habitats separated into three clusters (Fig. 4). *E. serotinus* differs from other bat species in its greatest ability to exploit man-made environments (e.g. villages). Further two clusters comprise groups of bat species. *M. emarginatus, M. mystacinus/brandtii, M. myotis/blythii* and *Plecotus auritus/austriacus* forage in cluttered and semi-cluttered habitats. Finally, *M. daubentonii, M. nattereri, Nyctalus noctula* and *P. pipistrellus* show high levels of flight activity at watersides.

The habitat preference of nine common species or species pairs (over 10 min+ in the total sample) was assessed by canonical analysis (Fig. 5). The total level of flight activity in particular habitats was used for this analysis. The highest preference of a single habitat type is apparent for the following species: *M. daubentonii* (watersides, i.e. streams and ponds), *M. mystacinus/brandtii* (forest), *E. serotinus* (villages) and *N. noctula* (open habitats, i.e. fields). *M. myotis/blythii* shows relatively close affinity to narrow meadow belts and linear
landscape elements. These two habitats may be considered semi-cluttered spaces for flying bats. Four species (*M. emarginatus*, *P. auritus/austriacus*, *M. nattereri*, and *P. pipistrellus*) show no strong habitat preference. Nevertheless, each of these bat species shows somewhat different requirements for foraging habitat.
Discussion

The use of bat detectors, like any other research method, has its internal constraints. A major problem in bat community research is posed by correct species determination of echolocating bats (Walsh & Harris 1996, Gannon et al. 2003). It is influenced by many different
factors, such as the duration of bat calls, presence of “whispering bat species”, and experience of the researcher. Nevertheless, bat-detectors, mist nets and harp traps are the only useful research methods for study of the activity of whole bat communities, and detectors are the most widespread method used at present. The authors tried to minimize the impact of technical and ecological constraints on the results of study in various ways, e.g. by using the same types of bat detectors, grouping species with similar echolocation calls, using reference records, as well as long-term experience in using bat-detectors in the field. A less complicated situation is found in investigating the flight activity of only one bat species (Rachwald 1992, Catto et al. 1996, Robinson & Stebbings 1997) and/or the activity of a group of selected and readily distinguishable species (von Zahn & Maier 1997, Gaissler et al. 1998, Bartonicka & Zuka 2003, Kusch et al. 2004).

Bats forage in various habitat types. Nevertheless, their preference for particular habitats depends on the presence of suitable food resources. The foraging activity of bats is affected by the distribution of prey not by the type of the habitat used (Brigham et al. 1992, Racey & Swift 1985, Warren et al. 2000, Kusch et al. 2004). Roosting requirements (number and distance of potential shelters) may also influence habitat utilization (Geggie & Fenton 1985). Many bat species forage only in the surroundings of their shelters. However, a habitat offering abundant food has no useful roosts in its vicinity the bats will seldom utilize it. On the contrary, if bats have the possibility of selecting from a large number of roosts they will choose those the closest to the food resources (Ryder 1989, Kusch et al. 2004). Bats prefer mainly diversified habitats and, on the contrary, their density is significantly lower in open landscape and/or inside dense forests (Macey & Fairley 1988, Kusch et al. 2004).

A preference for foraging in a single habitat type is very rare in insectivorous bats, as in general they use more habitat types, depending on actual food supply (Brigham et al. 1992), and they move between them during the night (Verboom & Spoelestra 1999).

Fig. 5. Habitat preference of nine common species or couple of species according to the total flight activity (results of canonical analysis). For abbreviation of bat species see chapter Results.
The most important foraging areas include all types of water bodies, from small streams and ponds to larger rivers, canals and lakes, as confirmed by our results. Their attractiveness is due to the great biomass of insects swarming over the water surface. From this point of view, stagnant water bodies are preferred to running ones (Frenckell & Barclay 1987, Mackey & Barclay 1989). Riparian vegetation is also important, mainly where watercourses run through open landscape (Rydell et al. 1994, Zahn & Mair 1997). In open agricultural landscape, patches of woods and linear elements (e.g. windbreaks) are also highly important as reservoirs of insects. Similar habitat types are only suitable where the bats can obtain enough food in agrocoenoses (Gaisler & Kolibáč 1992). In the opposite, this type of habitats was utilised by bats minimally in variable area of the Moravian Karst. Lowland deciduous and mixed forests are preferred among forest habitats. In such forests, open forest edges and clearings are favourite foraging areas of bats (Mayle 1990, Limpens & Bongers 1991, Walsh & Mayle 1991, Rachwald 1992). The extent to which bats make use of man-made structures is expressed in their habitat preference. A number of bat species forage in villages mainly in the vicinity of streetlamps where a high density of insects was registered (cf. Furlonger et al. 1987, Rydell 1992).

Different bat species can utilize different foraging strategies, which also indirectly influences the selection of foraging habitats. There is a clear relationship between a bat functional design, i.e. flight morphology and structure of echolocation calls, and its commuting and foraging behaviour including the structure of used habitats (Fenton 1990, Verboum 1998). Wing morphology confers mechanical and energetical constraints on flight speed and manoeuvrability (Norberg & Rayner 1987). Echolocation signals have evolved to optimize foraging efficiency of various bat species in particular habitats.

*M. daubentonii* shows a strong association with watersides and its activity is extremely high there. It is a typical trawler, gaffing prey from the water surface or aerially hawking insects over the smooth water surface (Warren et al. 2000). Turbulent rapid streams are used rather more for commuting flights than for foraging, as this species often forages in groups and creates group foraging territories. *M. daubentonii* has a considerable overlap in the structure of calls with *M. nattereri* and there might be some misidentifications. Nevertheless, *M. nattereri* was detected mainly foraging higher over the water surface in the vicinity of the riparian vegetation (deJong 1995). Its activity would also be underestimated due to silent calls and/or if the calls had a poor signal to noise ratio when the calls of *M. nattereri* are masked by the loud signals of *M. daubentonii* foraging groups.

*M. mystacinus/brandtii* were the species most frequent recorded in forests, as in Sweden where *M. brandtii* used the coniferous forest more than expected and the deciduous woodland in proportion to its area (deJong 1995). Generally, flight activity in forests is very low. *M. mystacinus/brandtii* also forage in the vicinity of water courses (von Zahn & Mair 1997) and they may be underestimated here, as with *M. nattereri*. The presence of both species i.e. *M. mystacinus* and *M. brandtii* in the region under study was documented by netting (Řehák et al. 1994). Together with *M. mystacinus/brandtii*, individuals of the genus Plecotus were often recorded in the forests. Most probably, these were to *P. auritus*, which prefers forest habitats (deJong 1995) whereas records from gardens within villages probably pertain to the sibling species *P. austricus* (Bauerová 1982). Similarly as in other pairs of sibling species, their echolocation calls cannot be differentiated in the field.

A relatively low activity was registered for *M. emarginatus*, a species foraging in cluttered and semi-cluttered habitats. This species behaved as a typical gleaner using edges of forests with a well-developed shrub layer adjacent to vertical rock walls surrounded by

---

279
shrubs. In these habitats, *M. emarginatus* will probably glean small arthropods, especially spiders (Bauerová 1986).

The species included in the *M. myotis/blythii* pair differ significantly in habitat preference and thus also in different prey selection – terrestrial (e.g. carabid beetles) vs. grass-dwelling (mostly bush crickets) (Arlettaz et al. 1997). Higher activity registered over the meadows should indicate the presence of *M. blythii* in the Moravian Karst. However, in the present study such sites were mostly narrow meadow belts surrounded by woods. In addition, only search calls were recorded there, and thus these bats may have been commuting specimens of *M. myotis*. During the past three years, telemetry has revealed that even *M. myotis* will forage in the open habitats of the Moravian Karst, including fields (Pokorný, Berková & Zukal, unpublished data). In addition, *M. blythii* is a very rare species in the area under study, recorded sporadically in the caves during hibernation and/or at cave entrances during autumn migrations (Re hák et al. 1994).

*E. serotinus* is able to exploit a wide range of habitats foraging mainly over streetlamps, in gardens as well as over ponds (Catto et al. 1996). As a typical semisynantropic species, *E. serotinus* differs from other bat species recorded in the Moravian Karst by the highest ability to exploit man-made environment (Verboom 1998). Only *N. noctula* is able to forage in similar habitats. Nevertheless, this species regularly used open habitats and was recorded flying very high over fields. At twilight, *N. noctula* often preys on swarming insects over the ponds but, later on, it appears in villages, catching prey in the vicinity of streetlamps (Rachwald 1992). This movement is influenced by the dwindling abundance of insects due to the falling ambient temperature in the natural habitats.

*P. pipistrellus* seems to be highly adaptive in foraging habitat preference in comparison with other bat species showing similar foraging strategies (Warren et al. 2000). *P. pipistrellus* forages both over water bodies and in riparian vegetation and, together with *E. serotinus* and *N. noctula*, use the parts of villages illuminated by streetlamps (Rydel 1992). Nevertheless, their activity is very low in very dense as well as in entirely open habitats (von Zahn & Maier 1997, Verbom & Spoelstra 1999).
